Elevated tropospheric ozone concentrations induce adverse effects in plants. We reviewed how ozone affects (i) the composition and diversity of plant communities by affecting key physiological traits; (ii) foliar chemistry and the emission of volatiles, thereby affecting plant-plant competition, plant-insect interactions, and the composition of insect communities; and (iii) plant-soil-microbe interactions and the composition of soil communities by disrupting plant litterfall and altering root exudation, soil enzymatic activities, decomposition, and nutrient cycling. The community composition of soil microbes is consequently changed, and alpha diversity is often reduced. The effects depend on the environment and vary across space and time. We suggest that Atlantic islands in the Northern Hemisphere, the Mediterranean Basin, equatorial Africa, Ethiopia, the Indian coastline, the Himalayan region, southern Asia, and Japan have high endemic richness at high ozone risk by 2100.

INTRODUCTION

Above- and belowground trophic interactions play pivotal roles in maintaining plant diversity. Plants respond to herbivores by various physiological mechanisms, affecting plant performance and plant-microbe interaction and potentially regulating ecosystem processes and community dynamics (1–3). Plant-soil feedbacks (PSFs) likewise involve interactions among plants, soil microbiota, and abiotic factors, affecting structural and functional features at different scales of biological organization. These effects allow plants to readily respond to environmental changes and mediate ecosystem processes (4). Trophic interactions depend on environmental conditions, so

changes in the environment may affect biodiversity and the functioning of terrestrial ecosystems (2, 4, 5).

Ground-level concentrations of ozone (O₃) increased considerably in the second half of the 20th century due to increased levels of NO_x, volatile organic compounds (VOCs), and radical precursors responsible for its production (6–8). For example, current O₃ levels in rural areas of the temperate and polar zones of the Northern Hemisphere (NH) have increased by 30 to 70% compared to 1896–1975 (6, 7). The O₃ concentrations have remained elevated (see the Supplementary Materials) but are also projected to remain high throughout the 21st century (9), raising concerns about O₃ phytotoxicity, despite policies for reducing precursor emissions. Many programs have documented the incidence of visible injury from O₃ in numerous field-grown species of forbs, shrubs, and trees worldwide, but O₃ has often not been included in global assessments of threats to biodiversity (5, 10). Preliminary analyses suggest that O₃ will continue to pose risks to terrestrial biodiversity at various trophic levels and ecosystem processes and feedbacks in the future (10).

Despite the progress in our understanding of numerous physiological mechanisms specific to plants for responding to O₃ (11, 12), we still know little about the responses of communities and ecosystems to O₃. Identifying plant mechanisms that may drive the structure and function of plant communities and interactions with insect and soil communities in O₃-polluted atmospheres is challenging, and the effects on the functioning and biodiversity of terrestrial ecosystems are underexplored (5, 10, 13).

This paper addresses how O₃ affects plant communities, plant-insect interactions, and PSFs and thus plant, insect, and microbial diversity (Figs. 1 and 2). We have four aims. (i) Review the relationships between plant ecological traits and susceptibility to O₃. We thus collated empirical evidence to determine whether O₃ affects the structure and diversity of plant communities depending on functional groups. (ii) Discuss how O₃ affects plant-insect interactions and whether ecosystem functioning and the structure and diversity

Fig. 1. Effects of elevated ozone (O₃) on aboveground ecosystem processes. Ecological processes occurring at the ecosystem and foliar levels in a natural (not polluted) ecosystem (A) versus an ecosystem disturbed by increased levels of O₃ (B). Gray icons represent the loss of insect or plant diversity but not for particular species. O₃ reduces the growth rate and biomass of plants (including forest trees) (I). Deciduous broadleaf species are usually more susceptible than evergreen broadleaf and needle-leaf species (I). O₃ can also reduce plant species richness and alter community composition (II). O₃ reduces the abundance of insect species but not species richness in forest ecosystems (III). O₃ and OH degrade biogenic VOC (BVOCs), thereby impeding plant-pollinator communication (IV). O₃-plant-insect interactions may be quite complex and species specific. O₃ inhibits isoprene emissions, increases monoterpene emissions in tolerant and evergreen species, reduces foliar size, induces foliage premature senescence (V and I), and increases plant susceptibility to insects and pathogens (I and VI). In other cases, O₃ induces the accumulation of phenolic compounds in leaves, discouraging herbivory by insects (thus reducing insect abundance), increases insect mortality, and inhibits the growth of insect body mass (VII). O₃ also alters foliar phytochemistry, thereby impeding insect oviposition (VIII).

of insect communities are threatened by O₃-caused changes in VOCs and foliar chemical composition. (iii) Assess how O₃ affects plant-soil interactions and thus soil ecosystem functioning, with special reference to plant litter, decomposition, nutrient cycling, and microbial biomass. The hypothesis that O₃ can affect microbial communities and diversity was verified by a series of studies demonstrating that PSF responses to O₃ can lead to changes in the community structure and diversity of soil microbes. (iv) Analyze global endemic richness of vascular plants versus predicted O₃ exposure by 2100 for assessing whether foci of the endemic richness of various biomes overlap with areas of high O₃ risk, with adverse effects on plant productivity. We use these discussions to seek to identify important gaps in our knowledge and to draw some conclusions about how O₃ can affect plant interactions with insects and microbiota and, thus, alter PSFs and community composition and diversity of plants, insects, and microbiota.

Plant-plant interactions: Are plant-community composition and diversity at risk from O₃?

Indicators of plant susceptibility to O₃

The main indicators of the susceptibility of plants to O₃ are stomatal conductance, specific leaf area, and genetically controlled defensive capacity (14, 15). Classification of plant species into tolerant and susceptible, however, is difficult because of their high intraspecific variation in tolerance (5, 16, 17). High intraspecific genetic variation has been detected in grasses and herbaceous and woody plants [e.g., *Phleum alpinum*, *Trifolium repens*, and *Plantago major* (16), as well as *Betula pendula* and *Populus* spp. (18)] and has been studied in detail in, for example, willows and silver birches (18). The genetic variation of O₃ tolerance in these species has been attributed to a range of factors, including foliar phenolic composition (19), effective pathways of ascorbate-glutathione detoxification, remobilization of amino acids (20), genetic plasticity, chemical composition of foliar

Fig. 2. PSFs under elevated ozone (O_3). A healthy holobiont in a clean atmosphere (with natural background O_3 levels), where mutually beneficial PSFs occur (A), versus a suppressed holobiont and disturbed PSFs due to O_3 (B). Gray icons represent the loss of microbial biomass but not for particular species. O_3 decreases root biomass, reduces the quantity, and affects the quality of foliar and root litter, potentially affecting litter-feeding soil macrofauna, decomposition, and cycling of nutrients. O_3 may influence the chemical composition of roots and soluble root exudates, including reduced exudation of some extracellular enzymes (e.g., β -glucosidase). The rate of decomposition can be increased or decreased species-specifically. Soil microbial biomass also decreases. O_3 alters the composition and structure of soil microbial communities, with fungi being likely more susceptible to O_3 than bacteria. Some N-fixing bacteria are promoted by O_3 , but N fixation is reduced by O_3 in other studies. Some denitrifying bacteria are likewise promoted by O_3 , and the abundance of some nitrifying bacteria can be either reduced or increased by O_3 . The decrease in microbial biomass disturbs the rates of N and C cycling as feedback, potentially reducing N_2O and storing less C in the rhizosphere. The changes in C and N cycling in PSFs may occur in tandem with changes in the cycling of other nutrients due to poor leaf and root litter as well as affected decomposition processes.

surface waxes (21, 22), stomatal closure, and foliar structural traits, such as apoplastic volume, thickness, and leaf dry mass per unit area (LMA) (18, 23). Model species such as *Arabidopsis thaliana* clearly indicate that O_3 tolerance is due to a unique set of alterations of various defensive mechanisms, e.g., signaling pathways, regulatory genes, plant hormones, antioxidants, and physiological processes (function and regulation of stomata) (24, 25). These indicators of tolerance can be useful for individual plants or plant mixtures but are challenging in studies at evolutionary and population levels. The selection for O_3 tolerance in the field is further complicated by the multiple environmental factors and stressors that usually affect plants, such as drought, salt, heavy metals, light, nutrient availability, and changeable meteorological conditions (16, 26, 27). Agrobiodiversity and the compositions of seminatural plant communities, among other factors, are often affected by management practices such as grazing, cutting, and fertilization, all of which further obscure the influence of O_3 .

Plant leaves are most exposed to elevated O_3 and have therefore been extensively examined for structural modifications and adaptations to elevated O_3 and associated plant susceptibility (5, 15, 16). The O_3 susceptibility in silver birch and trembling aspen (*Populus tremuloides*) has been associated with foliar thickness, i.e., the most susceptible genotypes had thinner leaves (28). An extensive survey of subtropical, temperate, and Mediterranean tree species found

that O_3 tolerance at the foliar level was associated with LMA, and a reduction in whole-tree biomass was linked to high stomatal flux per unit foliar mass, indicating high O_3 uptake per unit mass (29). High LMA and sclerophyllia can provide O_3 tolerance by (i) cross-protection (e.g., resistance to several stress factors such as drought), (ii) the so-called dilution effect (lower O_3 load per unit foliar mass), and (iii) a large apoplastic compartment, which is often associated with high antioxidative capacity (5, 15, 30, 31). Trichomes are foliar-surface structures that may provide protection against high levels of O_3 by acting as physical barriers or by physiological detoxification (32). LMA, sclerophyllia, and trichomes are relatively easy to measure and can, therefore, be widely used for assessing the threat of O_3 in the field.

Relationships between O_3 susceptibility and plant diversity

Studying how elevated O_3 affects plant diversity requires focusing on functional traits associated with ecological fitness, such as reproductive fitness (seed output), plant health, and competitiveness. The responses of plant communities to O_3 , however, are ultimately driven by changes in growth, physiology, biochemistry, or genetics at the level of individuals or species (10). Many indirect and well-known effects of O_3 on plants may lead to changes in community composition and diversity, including impacts on growth, plant vitality (assessed as crown defoliation), photosynthesis, stomatal conductance, water balance, the trade-off between biomass production

and defensive processes, flowering, competition, and susceptibility to pests and pathogens (5, 10, 33, 34). These impacts can ultimately reduce the ability of species of a plant community to compete (inter-specific competition) and the ability of communities to compete. Specific indicators of biodiversity, however, may not represent the direct effects of O₃ such as reduced biodiversity within a plant community but rather variations in the competition for resources among plant species.

Visible foliar injury induced by O₃ is an important attribute for epidemiological assessments because it manifests susceptibility of plants to O₃ and is the only indicator of adverse effects of O₃ that can be used for routine field surveys (10, 35). The visible foliar injury appears as chlorosis, necrosis, flecks, stippling, bronzing, and/or reddening (see the Supplementary Materials for more information). While it is difficult to distinguish whether chlorosis and necrosis are induced by O₃ or normal senescence in the field, a characteristic of O₃-induced symptoms is that they usually occur on interveinal areas of the upper leaf surface only and older leaves show the most symptoms. Species-specific visible injuries have been widely found in nature (10, 35–37), although evidence for the relationship between O₃-induced visible injuries and damage is contradictory and uncertain especially for forest trees (38). Visible injuries may be associated with negative impacts on fitness traits [e.g., the reduction of carbon (C) assimilation/allocation limits growth and seed production, making the species uncompetitive] (38). Little is known, however, about the relationship between short-term phenomena such as visible foliar injury and longer-term processes affecting plant-community structure and ecosystem biodiversity (5, 10).

Ozone susceptibility varies among plant functional groups

On the basis of ecological strategies of competition and survival, some susceptible plants may be affected more than nonsusceptible plants by O₃-induced stress and may thus be competitively penalized (17, 39–42). The degree of susceptibility differs widely among species but also functional groups (Table 1), although current rankings of O₃ susceptibility are based on the susceptibility of individual species (5, 17, 43) and the modeling of different indicators (44). For example, elevated O₃ may decrease the aboveground biomass of therophytes (annuals) more than non-annual plants (e.g., chamaephytes) (43), suggesting that variations in response of annual and perennial species in a community under O₃ are also important for long-term biodiversity effects. High oxidative stress induced by O₃ can also adversely affect the fitness of O₃-susceptible genotypes when combined with harsh inter- and intraspecific competition within communities, ultimately altering the timing of flowering and seed development and reducing the number and biomass of flowers in some species in a community (33, 45, 46). The community composition of terrestrial ecosystems may thus exhibit long-term changes, and plant diversity may be at risk (Fig. 1), especially in areas where O₃ occurs at potentially phytotoxic levels (Fig. 3).

Empirical evidence for O₃ threats to plant-community composition and diversity

Empirical evidence from several experiments conducted in different regions of the world indicates that O₃ can affect the structure and diversity of plant communities (table S1). Several experiments with open-top chambers (OTCs) in pasture communities exposed to O₃ (commonly up to twofold above the ambient O₃ concentrations) for two to four growing seasons have demonstrated changes in species composition (table S1), with some species being lost over time, and in community structure (42, 47–51). For example, there is evidence

Table 1. Evidence that the susceptibility of plants to O₃ is conserved at relatively high taxonomic levels. The reader may refer to the references for further details.

Susceptibility	Reference
Angiosperms > gymnosperms	(204)
Pioneer species > climax species	(205)
Temperate species > subtropical species	(12)
Therophytes > other Raunkiaer life forms (chamaephytes and hemicryptophytes)	(14, 43)
Deciduous trees > evergreen conifers	(5)

Plants tolerant to moderate salinity > plants of no saline habitats	(43)

for reduced plant species richness (total number of species), diversity (Shannon-Weaver index), and evenness of an early successional community due to exposure to ambient and elevated O₃ levels over two growing seasons (49). These elevated O₃ concentrations occur in highly polluted areas of NH nowadays. Solardome experiments have also suggested potential changes in the structure of grassland communities (33, 45). An O₃ treatment accounted for ≈40% of the variation in species composition (41). Reduced species richness (total number of species), diversity (Shannon-Weaver index), and evenness due to exposure to O₃ were particularly important over two growing seasons in an early successional community (49). The species richness of communities with different histories of O₃ exposure was similar, but the relative abundance of the dominant species differed among the communities (50). Changes in community structure due to past exposure to O₃ suggest that O₃ might have already contributed to changes in natural communities.

The use of free-air O₃ concentration enrichment (FACE) experiments can generate more realistic estimates of the impacts of O₃ on vegetation because the plants fully interact with the surrounding natural environment. A few FACE studies have assessed the impacts of O₃ (commonly up to 1.6-fold higher than the ambient O₃ concentrations) in subalpine and other types of grasslands after two to

Fig. 3. Ozone exposure levels and global plant endemic richness. Surface mean AOT40 [parts per million (ppm)-hour] for 2000–2003 (A) and for RCP2.6 (B), RCP4.5 (C), and RCP8.5 (D) by 2100, overlapping the global patterns of the endemic richness of vascular plants (number of species of vascular plants per 10,000 km²) across biogeographic regions worldwide (except Antarctica). RCP represents a representative concentration pathway, and AOT40 represents accumulated ozone exposure above a threshold of 40 parts per billion (ppb). Data sources: (9) and (197). The ozone maps are from (9).

seven growing seasons (table S1). Some experiments found O₃-induced shifts in the fractions of plant functional groups, changes in species composition depending on the functional component, and increased abundance of some species such as *Nardus stricta* (52). Empirical evidence from long-term FACE experiments, therefore, supports the suggestions from OTC experiments that O₃ induces alterations to the structure and species composition of grassland communities.

Forbs are generally more susceptible to O₃ than grasses, but the relative abundance of a grass species may decrease, depending on potential interacting environmental factors (table S1). Note that some species may increase in abundance and others may decrease but without necessarily a large loss of species richness or a shift in their distributional evenness (53). These changes in community composition may also lead to changes in the nutritional value of vegetation used for animal consumption. For instance, reductions

in the legume fraction, but not the grass fraction, of harvested biomass as a result of elevated O₃ exposure occurred in intact and managed pasture (54, 55), *T. repens*–*Lolium perenne* mixtures established under field conditions from seed (56), and *T. repens*–*L. perenne* established in mesocosms (57). Similarly, reductions in the clover/grass ratio due to elevated O₃ appeared in *T. repens* and *L. perenne* (58) and for *T. repens* and *Festuca arundinacea* (59). Comparable reductions can also occur if the aboveground biomass of the grass component increases due to reduced competition from the legume. Altered pasture quality from samples analyzed from seven component studies also occurred (60). This was the result of species composition alterations and the nutritional quality change of individual species within the community.

The hypothesis of impacts on community composition associated with O₃ was also supported by an assessment of the impacts on community composition at 64 field sites selected from the U.K. National

Vegetation Classification of U4 “*Festuca ovinae*–*Agrostis capillaris*–*Galium saxatile* grasslands,” which represent calcifugous grasslands, widely distributed in the British Isles (table S1) (53). The use of genetic markers and DNA fingerprinting in wild populations also demonstrated that genetic diversity is declining in areas with high levels of O₃ [reviewed in (5)]. These studies suggest potentially changing diversity in the real world. Recent technological developments are providing powerful tools for monitoring the loss of biodiversity in vegetation with various plant functional groups, e.g., remote sensing and hyperspectral imaging techniques combined with drones (61); drone techniques are particularly useful in wetland ecosystems. These techniques can potentially more robustly assess the global threat of O₃ to biodiversity in the future.

Some studies have reported negligible or no significant effects on species composition, community structure, or diversity. Several factors, which can affect the estimated impacts of O₃, such as OTC environments, can affect the species composition of pastures (55). Within-family competition can also be a major driver of the general response of a community (42), and competition between species can be affected by both O₃ and the mixing ratio of the individuals within a community (62). The compositions of species with low abundances may also not greatly change, even if the species are strongly affected by O₃ (52, 63). The outcome of inter- or intraspecific competition also depends on other environmental factors such as soil-water content (62), soil nitrogen (N) content (42, 52), and spatial heterogeneity (64). A mixture of contaminants may also occur in the environment, and multiple co-occurring environmental contaminants may have larger effects than the effects of single contaminants (53). A new generation of studies accounting for various co-occurring factors is therefore needed to provide a basis for assessing real-world risks.

Plant-insect interactions: Is insect community composition and diversity at risk from O₃?

Foliar quality drives plant-insect interactions

Ozone can affect both the foliar content of N, a major nutrient driving insect dynamics (65), and secondary metabolites. For example, several studies show that elevated O₃ enhanced the concentration of lignin, a key secondary metabolite determining the palatability of biomass to insects (66). Secondary metabolites play important roles in the defense of plants against herbivores by deterring feeding and reducing digestibility by being toxic at high concentrations (2, 67–71) but may also attract herbivores at lower concentrations (70, 72). Elevated O₃ doses that exceed the toxicological threshold inhibit photosynthesis and thus the biosynthesis of secondary metabolites, whereas low O₃ doses that are below the toxicological threshold stimulate defensive signaling pathways and induce the biosynthesis of secondary metabolites (21, 73). Insect herbivores are expected to damage plants more if O₃ decreases the rate of C assimilation so that less C is available for C-based defensive chemicals (74). Numerous studies have demonstrated that O₃ affects phenolics and terpenes, especially in angiosperms (75), although different groups of phenolics and terpenes may respond differently to O₃ (19, 76, 77). Despite the recent advancements in the understanding of O₃ effects on foliar quality, O₃ effects on latex and other constituents of saps exuded from damaged tissues remain completely unknown, although plant latex plays an important role in defense against herbivores (78).

Plant defense modulates insect growth and development directly via toxic secondary metabolites or indirectly by recruiting the natural

enemies of insect pests via herbivore-induced plant volatiles and extra floral nectar (67, 79, 80). For example, the mortality of gypsy moths increased when fed with leaves treated with O₃ (81). A recent study also found that the increase in body mass in *Samia ricini* larvae was inhibited when the larvae were fed with cauliflower (*Brassica oleracea*) leaves treated with O₃ (65), similarly to *Pieris brassicae* reared on *Brassica nigra* (82). This inhibition was due to the effect of O₃ on foliar quality and could, thus, affect herbivory levels by overcompensating for the poor nutritional quality of the tissues (65, 83). These effects suggest potential shifts between generalist species, which can adapt easier to plant defensive compounds and thrive in a wide variety of environmental conditions, and specialist species, which have a limited diet and can thrive only within a narrow range of environmental conditions (84).

Shifts in secondary metabolites under elevated O₃ may lead to changes in relative insect performances, including feeding and ovipositional preferences, longevity, and the ability to reproduce, potentially influencing the population density and community composition of the insects (73, 81, 85). Recent studies of a community of trees grown in a FACE system for 5 years, however, found that populations of different species of insects, with different host plants, decreased significantly in elevated O₃ (74, 86). These studies suggest that these decreases were not due to foliar palatability, also confirmed by laboratory assays (74, 86, 87), or to direct negative effects of O₃ on insects (88), leading to the suggestion that VOCs played an important role in plant-herbivore interactions under O₃ (89). These observations agree with those from other studies of different plant-insect systems (85).

Impacts of O₃-induced changes in VOC emissions on insect dynamics

Biogenic VOCs (BVOCs), i.e., VOCs emitted by plants, play important roles in a range of conspecific and heterospecific interactions and plant survival (90–92). They are emitted by most plant components, both above- and belowground (roots), and provide pivotal ecological cues detectable over a range of distances (93–96). Typical BVOCs include isoprene, terpenes, green leaf volatiles, carbonyls, organic acids, halides, sulfurous compounds, and benzenoids (97). Ozone can induce, reduce, or have no effect on BVOC emissions, depending on the species and conditions of exposure (98–100). Isoprene emissions are typically inhibited under elevated O₃, but monoterpene emissions of O₃-tolerant and evergreen species are stimulated (101).

Interactions involving O₃, BVOCs, and insects are highly complex. Ozone can react with a multitude of VOCs in the atmosphere, breaking them down into mostly unknown reaction products, which may impair communication between plants and insects mediated by volatiles and may compromise pollination (82, 93, 102–105). For example, a laboratory study assessing the effects of O₃ on the orientation of a beetle (*Acalymma vittatum*) to flowers reported that O₃ levels <80 parts per billion (ppb) did not affect orientation, whereas levels >80 ppb disrupted orientation toward floral volatiles (106). Similar results were found for the attraction of other beetles (*Agelastica coerulea*) to leaves (89). Both elevated O₃ (107) and diesel exhaust (108), which comprises some precursors of O₃, have recently been reported to rapidly degrade floral volatiles. The distance over which floral scents can be detected by pollinators thus decreased, negatively affecting the orientation of the pollinators toward floral food sources (107).

Behavioral tests run at elevated O₃ concentrations indicated that elevated O₃ could also considerably alter the composition of volatile

blends induced by herbivory and consequently alter tritrophic interactions by influencing the behavior of the natural enemies of the herbivores (109–111). The results from these studies, however, were inconsistent. For example, O₃ affected plant volatile bouquets induced by herbivory, but the changes did not affect the orientation of parasitoids, indicating a minimal role of oxidation products in signal perception for this system (109). A combination of elevated O₃ and *P. brassicae* larval feeding on *B. nigra*, however, induced substantially larger volatile emissions than either stress alone, which decreased the attractiveness of the plants to the parasitoid *Cotesia glomerata* relative to plants exposed to herbivores alone (111). Exposure to elevated O₃ may also typically reduce insect oviposition on host plants (86, 112), which may be influenced by multiple mechanisms such as the degradation by O₃ of specific VOCs that stimulate oviposition (105, 113).

Understanding the knock-on effects on insect diversity and the impact of O₃-induced VOC emissions on insect diversity is needed, despite the growing number of studies addressing the effects of O₃ on the composition of BVOC emissions and specific ecological interactions. The impact of O₃-induced VOC emissions on insect diversity should also be studied further.

Empirical evidence for O₃ risks of insect community composition and diversity

Numerous studies have addressed how O₃ alters insect performance by modifying secondary metabolism and VOC emissions, but the impacts of O₃ on insect diversity remain relatively understudied. The fecundity of individual insects does not predict the responses of populations or communities to O₃ (114), but three studies of the effects of O₃ on insect diversity suggest that O₃ can alter species abundance and community structure, thereby threatening diversity (50, 115, 116). For example, an examination of >47,000 insects from four orders and 83 families sampled in a FACE system at regular intervals over four growing seasons found that O₃ tended to increase the abundance of phloem-feeding herbivores and decreased the abundance of chewing herbivores and parasitoids in aspen (115). This study also found that elevated O₃ reduced the total abundance of insects (17%) compared to ambient O₃, with prominent effects on parasitoids such as Braconidae (−33%), Chalcidoidea (−26%), Figitidae (−59%), and Ichneumonidae (−41%) (115). Arthropod communities also changed in two experiments when seeds from a community of natural plants previously exposed to filtered air, 90-ppb O₃ or 120-ppb O₃, with episodic patterns of varying daily peak concentrations over four growing seasons, were used to re-establish the plant community in a new environment with low-level O₃ pollution (50). The carnivore/herbivore ratio particularly increased (increased abundance of carnivores) with increasing historical levels of O₃ in the 2 years following historical exposures (50). The effects on insect abundance and species richness are specific to plant species and vary temporally (116). More studies are needed, but these results suggest that O₃ may influence biotic communities and pose a threat to biodiversity even years after exposure.

Interactions between plant and soil microbiota: Are microbial community composition and diversity at risk from O₃?

Plant-microbe coevolutionary relationship

Diverse communities of bacteria and fungi live near and on the surfaces of plant roots (rhizosphere) and leaves (phyllosphere) and in internal plant tissues (endosphere). Beneficial microbes help plants

to acquire water and nutrients, defend against pathogenic microbes, tolerate abiotic stress (including drought and O₃ and other air pollutants), adapt to environmental changes, establish mycorrhizae, and regulate plant growth (117–121). Microbes can regulate plant growth directly by releasing phytohormones or organic growth promoters, contributing to ecosystem processes, such as N fixation, ammonia oxidation, and phosphate solubilization, or indirectly by producing biocontrol compounds, such as antibiotics, siderophores, and enzymes, or signaling compounds (121–123). Microbes, in return, benefit from a stable niche, and the supply of primary and secondary metabolites and C from root exudates (123, 124). Microorganisms are evolutionarily older than land plants, and our current understanding is that plants are coevolving species assemblages—holobionts (Fig. 2), consisting of plants and their microbiota (125). The long coevolution of plants and their associated microbiota has likely led to phylogenetically and functionally divergent microbiomes in different environments and climatic zones. Our current knowledge of the impacts of O₃ on plant microbiota and biodiversity is mainly restricted to rhizospheric processes.

Plant-soil feedbacks

An extensive body of literature addresses the interactions between plants and biotic and abiotic soil properties, known as PSFs (4). The effect of increasing atmospheric concentrations of O₃ on these interactions, however, has rarely been studied (10, 13). A few studies have investigated the effects of manipulated O₃ levels on community structure and composition and the function of soil microbial communities, but the results have been inconclusive (126–131), perhaps due to varying durations of the experiments or other experimental factors such as the facilities used for exposing plants to O₃, ecosystem type, and type of management (132). Many of these new studies, however, suggest potentially important impacts of elevated O₃ on PSFs, including soil microbial diversity and decoupled PSF interactions (Fig. 2).

Soil ecosystem functioning

Elevated O₃ can modify resource allocation between above- and belowground parts of the plant, an important response in all plants under O₃ stress (13, 133). A meta-analysis showed that O₃ generally inhibits the allocation to roots, relatively to shoots, albeit a variable phenomenon (133). A more recent analysis of 239 data entries of dry root mass of woody plants revealed that 40% of the entries reflected a statistically significant decrease and only 3% of the entries reflected a statistically significant increase (13). Likewise, an analysis of 104 data entries of root/shoot biomass ratio showed that 27% of the entries reflected a statistically significant decrease and only 5% of the entries reflected a statistically significant increase (13). Hence, it appears that elevated O₃ generally reduces the allocation of resources to roots more than to shoots, suggesting potential feedbacks to the soil ecosystem.

Rhizospheric microbial communities are highly diverse and have a fundamental role in nutrient acquisition, water economy, growth, and disease tolerance (118). Elevated O₃ reduces the allocation of C derived from the soil, which reduces the amount of resources for heterotrophic microbes and thereby affects belowground processes driven by microbes (132, 134, 135). O₃ can thus modify decomposition rates, activities of soil enzymes, root turnover, rhizodeposition (all material lost from plant roots and deposited into the soil) and belowground cycling of C and N, although the magnitude and direction of the influence are plant specific and depend on various environmental conditions other than O₃ (136–139). The role of

rhizodeposition is particularly important in northern biomes, where productivity is often strongly limited by the uptake and cycling of N (140). Exudation of other molecules such as chelators or organic acids is also crucial for the acquisition of phosphorus or microelements, but they lack experimentation regarding their role in O₃ effects.

Many studies have reported that O₃ accelerates foliar senescence, thereby changing the timing of litter deposition, and reduces the amount of leaf litter due to diminished foliar area (13, 141, 142). O₃ can also affect litter quality (12, 13, 143). A series of experiments on the effects of O₃ on nutrient translocation from senescing to younger leaves identified species-, soil-, and study-specific changes in the levels of micro- and macronutrients in the foliar litter, which appeared early during stress, altering ecological stoichiometry (144, 145). More studies are needed to draw general conclusions about these highly complex phenomena. These changes in the amount and quality of litter could affect soil macrofauna that feeds on litter, including detritivores [e.g., (143)].

Ozone reduces rhizodeposition because ecosystems exposed to elevated O₃ support a lower net primary productivity, similar to leaves. The rate of turnover of fine roots may also be higher, which may also affect decomposition (13). Many experiments have found that O₃ affects the chemical composition of fine roots, such as decreasing or increasing the contents of monosaccharides, total soluble carbohydrates, and total sugars, depending on the severity of stress (13). The levels of fatty acids, starches, and nutrients were also affected but not consistently in direction or magnitude, which are expected to vary with time and stress level (13). Ozone influences the chemical composition of both roots and soluble root exudates (146, 147). All these alterations can lead to species-specific changes in the rates of decomposition (138, 148).

Recent advances show that elevated O₃ alters the expression of microbial genes involved in C cycling, which, in turn, likely affects C cycling regulated by microbes (149). For instance, in two Chinese wheat cultivars exposed to elevated O₃ in a FACE system, the abundance of C cycling genes was generally decreased in both cultivars (including *fts* genes involved in the reductive acetogenesis pathway), although the abundance of a few genes increased in both cultivars (*mcrA* and mannanase and xylanase genes) or one of the cultivars (*amyX*, *nplT*, and *lip* genes in one cultivar; *pcc*, *aceA/B*, bacterial *ara*, and carbon monoxide dehydrogenase and phenol oxidase genes in the other cultivar) (149). Ozone can also reduce the ability of microbes to use C sources, especially in the rhizosphere, as indicated by the reduced signal intensity of some C degradation genes (e.g., related to hemicellulose, aromatics, and chitin) detected in a soil depth of 0 to 5 cm (129). The excretion of some extracellular enzymes involved in C metabolism (e.g., β -glucosidase) can be similarly suppressed by O₃ (150, 151), reducing the availability of C sources, which can also decrease the methanogenic activity of microbes in paddy fields (152). Ozone generally decreases C cycling by decreasing C-based exudation caused by a reduced translocation of photosynthates to the roots (13).

Ozone can also impair N cycling in soil driven by microbial activity (139, 150, 153–157). For example, N fixation by legumes can decrease in response to increasing O₃ concentrations (158). Several studies show that N-fixing plants (e.g., legumes) grown within multispecies plant communities can be more sensitive to O₃ than their co-occurring species (table S1), although it remains elusive how O₃ affects their N-fixing capacity in these multispecies communities. Ozone can also negatively affect N₂O emissions from meadows and

soybean fields (159, 160) and rice and wheat fields (161–163), suggesting that reduced denitrification due to decreases in plant-derived C inputs induced by O₃ may play a dominant role. The direction of the effects of O₃ on N₂O emissions is also driven by the system of cultivation (163). Recent advances suggest that O₃ can reduce the expression of microbial genes involved in N fixation, denitrification, and N mineralization associated with legumes (129), including decreased abundances of *nirK*, *nirS*, and *nosZ* (which are widely used to describe denitrifier communities) and *amoA* (an indicator of nitrifier communities) (160). Reduced availability of soil N and/or labile C for nitrifiers or denitrifiers may account for these observations in the abundances of genes associated with N cycling. The effects of O₃ on the cycling of soil N, however, clearly vary among plant genotypes or cultivars depending on their susceptibility to O₃ (139, 149, 163). These findings demonstrate the decoupling of PSF interactions by O₃.

Several studies suggest that O₃ usually decreases soil microbial biomass (127, 150, 152, 164–166). The negative response of microbial biomass to O₃ is most likely due to a reduction in root biomass and substrate availability (13). O₃ can reduce both fungal biomass and the ratio of fungi to bacteria, suggesting that fungi may be more susceptible than bacteria to O₃ (149, 165, 166). Elevated O₃ can significantly decrease microbial biomass in microaggregates (inhabited predominately by bacteria) relative to macroaggregates (132), suggesting that bacteria in microaggregates may be more susceptible to O₃. Ozone, however, increased microbial biomass in a community dominated by sedges (167), perhaps due to an increase in substrate availability, because O₃ slightly increased the total number of sedge leaves toward the end of the experiment, and/or to a faster turnover of fine roots caused by O₃ (168). A decrease in soil microbial biomass would also contribute to a suppressed holobiont and disturbed PSFs (Fig. 2).

Empirical evidence for O₃ threats to microbial community composition and diversity

Elevated O₃ can alter the composition and structure of soil microbial communities (127, 129, 130, 165, 166, 169–171). For example, 11 years of exposure to elevated O₃ doubled the ratio of Basidiomycota to Ascomycota in soil microbial communities (128). The relative abundances of bacteria at the order level in the phylum Actinobacteria (which may promote the degradation of recalcitrant substances) increased under O₃ (130). O₃ also reduced the relative abundance of bacterial groups belonging to the family Rhodospirillaceae and the order Clostridiales in rice systems (169). Further studies have recently reported the effects of O₃ on bacteria that facilitate the oxidation of ammonia, the rate-limiting step of nitrification. Elevated O₃ decreased the relative abundances of some nitrifiers (e.g., Proteobacteria and *Nitrospira*) but increased those of some denitrifiers (e.g., *Acremonium* and *Bacillus*) in soils growing *Machilus ichangensis* and *Taxus chinensis* (127). O₃ likewise increased the relative abundances of some nitrifying bacteria (e.g., Nitrososphaeraceae, Nitrospiraceae, Nocardiodaceae, and 0319-6A21) and N-fixing bacteria (e.g., Sphingomonadaceae, Rhizobiaceae, Termomonosporaceae, Micromonosporaceae, Streptomycetaceae, and Bradyrhizobiaceae) in the soil microbial community of a maize field (131). The abundance of microbes is an important indicator of N mineralization (172), and these results suggest that the effects of O₃ on microbial structural diversity can affect N mineralization.

The structure of microbial communities may be affected by the soil environment and plant functions. Decreases in root exudation

caused by elevated O₃ represent a plausible mechanism by which plants could modulate their interaction with microbes. Root exudates have an important role in plant-microbe interactions and help to determine the composition of the rhizospheric microbiome (173–175). Plants generally exude up to 20% of the fixed C and 15% of the N, which includes an array of simple molecules such as sugars, organic acids, and secondary metabolites and complex polymers such as mucilage (174, 176). The amount and composition of root exudates vary among plant genotypes. Root exudation is modulated by various abiotic stresses (177, 178). For example, microbial composition differed between maize genotypes, a phenomenon linked to differences in the amount of root exudation induced by O₃ (131). Few studies, however, have focused on the effect of O₃ on the relationships between root exudates and soil bacterial communities, so our understanding of the response of soil microorganisms to O₃ is incomplete.

The alpha diversity of soil fungi (especially ectomycorrhizae), bacteria, and archaea is often reduced by O₃ as an indirect consequence of changes in plant (and rhizospheric) structure and function caused by elevated O₃ (130, 179–182). Ozone in other cases, however, has increased microbial alpha diversity (130, 183, 184), highlighting the degrees to which the literature remains inconclusive and additional studies are needed for a comprehensive mechanistic understanding.

Ozone risks by 2100 and global biodiversity: Model predictions

Rationale

The previous sections documented that the effects of O₃ on insects and microbiota were mediated by plants and that the effects of O₃ on plants could affect the composition and diversity of plant, insect, and microbial communities (Figs. 1 and 2). The impacts of O₃ on plant diversity is not clear, but the evidence of indirect impacts on the diversity of plant microbiota is much clearer, suggesting that microbial diversity may be at a higher O₃ risk than plant diversity. Plant biomass, a trait critical to fitness that also indicates permanent adverse effects of O₃ (17), can be used as an indicator of the threat of O₃ to the health of the plant, insect, and microbial communities. The productivity of plant communities, such as in predominant global forests, is also positively correlated with species richness (185). We identified areas with overlapping O₃ risk and high terrestrial endemic richness for vascular plants under scenarios of representative concentration pathways (RCPs).

Methodology

Projected changes in O₃ vary considerably among models (186) and scenarios of emission of O₃ precursors (9). The latest emission scenarios, the RCPs, were developed for the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (187). The RCP scenarios include various assumptions on climate, policies of energy access, and changes in land cover and use (188). Different RCP scenarios lead to different concentrations and emissions, e.g., CH₄, O₃ (even stratospheric O₃ inputs), and emissions of NO_x from lightning, associated with climate change, all of which affect O₃ levels. The RCPs have been described elsewhere (9, 186, 189).

Sixteen global or regional chemical models within the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) were validated and used to evaluate projected changes in air quality under various scenarios of emission and climate (186, 189). On the basis of (9), we selected the global three-dimensional (3D) chemistry transport model MOCAGE (Modèle de Chimie

Atmosphérique à Grande Echelle) among the 16 ACCMIP models to assess the worldwide threats of O₃ to plant endemic richness.

MOCAGE is a global 3D chemistry transport model with a high grid resolution (0.5° by 0.5°), which provides numerical simulations of the interactions between dynamical, physical, and chemical processes in the troposphere and lower stratosphere (190). It uses a semi-Lagrangian advection scheme to transport the chemical species (190). MOCAGE reproduces well the spatial pattern of O₃ exposure at the global scale, e.g., in high-elevation areas or areas downwind of O₃ precursor sources (9). The MOCAGE historical runs cover the period 2000–2003, while the time slice of RCPs is centered around 2100. MOCAGE can simulate 110 gas species including VOC species as well as soil and lightning NO_x, with a horizontal resolution of 2° by 2°, and includes 47 vertical pressure levels from the surface up to 5 hPa. MOCAGE simulates biogenic emissions of hydrocarbons from vegetation (isoprene, monoterpenes, and other VOCs) and also parameterizes dry deposition of hundreds of compounds including O₃ (190). A shortfall of the MOCAGE model is that it overestimates O₃, especially near sea surfaces, essentially in NH (190, 191). This phenomenon was due to limitations of the thermodynamic equilibrium hypothesis in a marine atmosphere and an overestimation of NO_x emissions in the lowest part of the troposphere, especially in the winter months (190, 191). It may result from a positive bias in OH and CO emissions at the south of the Equator, which are mainly from a biomass burning origin, and are too strong (191).

The O₃ exposure-based index AOT40 [parts per million (ppm)·hour] is a metric used to assess the potential O₃ risk to vegetation from local to global scales and adopted by European regulatory agencies (192–194). AOT40 is less biologically relevant than flux-based metrics because, among other reasons, it does not incorporate species-specific O₃ influx (11). However, O₃ flux information can be obtained for only few ecotypes of (semi)natural plants, thus not permitting reliable O₃ flux estimates across large regions of the globe. Global flux data for (semi)natural vegetation, which is the focus of this study, are not available. Furthermore, mapping global-scale O₃ flux at high spatial resolution cannot be practically performed because of physical scarcity of data, such as hourly meteorological data, hourly soil moisture, dominant tree species per pixel, and stomatal conductance per dominant species. Moreover, world-leading agencies base regulatory ecological risk assessment upon estimated environmental concentrations (exposures) and not upon dose intake by organisms (influx), including the Deterministic Approach and the Probabilistic Approach [e.g., U.S. Environmental Protection Agency, Scientific Advisory Panel of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), Ecological Committee on FIFRA Risk Assessment Methods; www.epa.gov]. AOT40 is computed as the sum of the hourly exceedances above 40 ppb, for daylight hours (radiation, >50 W m⁻²) over vegetation- or species-specific growing seasons (195), namely, April to September for temperate climates (e.g., Europe) and all year round for Mediterranean, subtropical, and tropical-type climates (196). On the basis of (193), we calculated AOT40 for a model grid (8:00 to 20:00, local time) for all days of the year. A critical level of 5 ppm·hour calculated over the growing season has been recommended for the protection of trees (5% reduction, total biomass) and (semi)natural vegetation dominated by perennials (10% reduction, above- or belowground biomass and/or cover of individual species) (195). We selected this level as a stringent reference point for both annual and perennial (semi)natural vegetation; a level of 3 ppm·hour (195) would produce exceedances of critical

level throughout NH. Details of the O₃ data used and the procedure followed are provided by (9).

Kier *et al.* (197) analyzed the “endemism richness” of vascular plants (i.e., ferns, gymnosperms, and angiosperms) in large datasets and maps across 90 biogeographic regions worldwide (excluding Antarctica) using a standard area of 10,000 km². This index (endemism richness) combines both endemic and species richness and is considered superior to species richness or species endemism, and it can indicate the specific contribution of an area to global biodiversity (197). The dataset contains the full spectrum of abiotic conditions and includes all major biomes. We used the dataset provided by Kier *et al.* (197) to map the endemism richness of <5, 5 to 10, 10 to 20, 20 to 50, and >50 species of terrestrial vascular plants per 10,000 km². Mean richness for mainland areas was 18.2 species per 10,000 km², so we created these arbitrary categories and considered an endemic richness of ≥20 species per 10,000 km² to be high, i.e., exceeding the average endemic richness (see the Supplementary Materials).

RESULTS AND DISCUSSION

AOT40 averaged 31.8 ppm-hour in NH and 3.5 ppm-hour in the Southern Hemisphere (SH) in the 2000s (Fig. 3A). In the early 2000s, AOT40 below the critical level of 5 ppm-hour occurred mainly in the SH: South America, Pacific islands, the Cape region of South Africa, Madagascar, Polynesia-Micronesia, Melanesia, Indonesia, the Philippines, Australia, Tasmania, New Caledonia, and New Zealand (Fig. 3A). Higher O₃ burdens (AOT40, >25 ppm-hour) have been simulated for areas at high elevations, e.g., the Rocky and Appalachian Mountains and the Tibetan Plateau, and for Greenland, northeastern Siberia, the Mediterranean Basin, and areas downwind of precursor sources, e.g., southern Asia (Fig. 3A).

Changes in AOT40 compared to the early 2000s were –60% (NH) and +69% (SH) for RCP2.6 (most optimistic), –28% (NH) and +203% (SH) for RCP4.5, and +67% (NH) and +449% (SH) for RCP8.5 (most pessimistic). Surface AOT40 for RCP2.6 would decrease worldwide, except in equatorial Africa, where AOT40 was higher (Fig. 3B). Mean surface O₃ concentrations decreased most where historical O₃ concentrations were high. The O₃ foci (AOT40, >25 ppm-hour) for RCP2.6 were in Greenland, India, the Near East, and equatorial Africa (Fig. 3B), but the vegetation in Greenland was very limited. AOT40 for RCP4.5 was slightly lower than historical runs, except over Canada and eastern Asia (particularly Siberia)

where a high increase was observed (Fig. 3C). The surface O₃ levels and AOT40 were higher for RCP8.5 than historical runs and increased the most in northwestern United States, Greenland, the Mediterranean Basin, the Near East, and eastern Asia (Fig. 3D). AOT40 greatly exceeded 25 ppm-hour worldwide, except in Central and South America and Australia (Fig. 3D).

AOT40 for the three RCPs did not change significantly in SH. MOCAGE indicated that the critical levels for the protection of perennial (semi)natural vegetation for RCP8.5 based on AOT40 (5 ppm-hour) would be exceeded over many areas of NH by as much as 10-fold, despite improvements for RCP2.6 and RCP4.5.

AOT40 is expected to be high (>5 ppm-hour) by 2100 for 23 to 51% of the land areas with an endemic richness of 20 to 50 or >50 species per 10,000 km², depending on the RCP (Table 2). Only 4% of the land areas with an endemic richness of >200 species per 10,000 km², however, is projected to be exposed to high AOT40 values (>5 ppm-hour) and only for the most pessimistic scenario, RCP8.5 (Table 2).

All NH areas with very high endemic richness (>50 species per 10,000 km²) in the 2000s overlapped with high O₃ exposures (>5 ppm-hour), except Central America, northern South America, and the Philippines. Plant endemic richness was high in regions with a Mediterranean climate, and regions in NH where endemic richness was high (e.g., California, the Mediterranean Basin, and Ethiopia) had high O₃ levels in summer (198, 199).

A comparison of the global distributions of the endemic richness of vascular plants (>20 plant species per 10,000 km²) where AOT40 was >5 ppm-hour for the three RCPs indicated that both endemic richness and O₃ risk were high for NH Atlantic islands in the latitude band 15° to 45°N (e.g., the Canary Islands, Azores, and the Caribbean), the Mediterranean Basin, equatorial Africa, Ethiopia, the Indian coastline, the Himalayan region, southern Asia, and Japan.

Unresolved questions

A gap of knowledge exists in O₃ effects on natural and seminatural communities in tropical and subtropical environments; thus, these studies are encouraged. The long-term impacts of O₃ on biodiversity remain completely unknown, especially in terms of global biodiversity. A new generation of long-term “real-world” experiments designed to study the effects of O₃ on biodiversity are greatly needed. The complex structure, physiognomy, and high biodiversity of southern biomes are obstacles to conducting field or laboratory studies of this subject.

Table 2. Land areas for three ranges of the endemic richness of vascular plants exposed to high O₃ exposures (AOT40, >5 ppm-hour) by 2100 estimated using three RCPs.

	Land area exposed to AOT40 > 5 ppm-hour (%)			
	Historical	RCP2.6	RCP4.5	RCP8.5
Area with 20–50 species per 10,000 km ² (15.1% of total land area)	41.7	23.9	29.9	41.7
Area with >50 species per 10,000 km ² (11.4% of total land area)	37.7	23.2	23.2	51.3
Area with >200 species per 10,000 km ² (1.8% of total land area)	0.0	0.0	0.0	4.4

Can elevated O₃ alter the ecological plasticity of wild and semi-wild plant species? Potential selection pressure due to plant-plant competition under O₃ is likely weak and will be difficult to demonstrate. Previous studies have reported controversial results (16, 200) due to the high intraspecific variation of many species (5). Little evidence has been found for the impact of temporal changes in O₃ concentrations on diversity. Understanding and improving the tolerance to O₃ are more advanced for crop plants than wild and semi-wild species, but the tolerance of genetically improved plants to O₃ has rarely been demonstrated in the field (201). The use of genetic markers and DNA fingerprinting in wild populations has demonstrated that genetic diversity is decreasing in areas with high O₃ levels [reviewed in (5)], which may lead to reduced ecological plasticity in changing environments. Population differentiation studies at high-risk areas under future scenarios may provide further insights and are thus encouraged. Limited information is yet available for the impacts of O₃ on mosses, ferns, lichens, algae, and fungi, although current data suggest high tolerance to O₃ for many of these organisms (5). More research is needed to understand the role of belowground processes and phyllospheric microbiota for assessing biodiversity.

Can O₃ affect insect diversity? The effects of elevated O₃ on insects could be indirect and would depend on the magnitude of change in the quality of the host plant (bottom-up factors) and/or the impact on natural enemies (top-down factors) (83). Elevated O₃ may affect populations of natural enemies by shifts in the diversity, abundance, and quality of prey or changes in behavior that may affect finding hosts (85, 115). Information about the temporary and long-term impacts of elevated O₃ on insect diversity remains elusive.

Can elevated O₃ alter the diversity of phyllospheric microbiota? The differences in the composition of microbiota from different plant tissues represent an adaptation to different plant niches and the specific function of the tissue, such as C assimilation in leaves and the uptake of water and nutrients by roots. The atmospheric environment has direct contact with the phyllosphere, which forms the largest area of bioactive surfaces on Earth, at the interface between the plant and atmosphere, mediating plant responses to a changing environment (202). The phyllosphere is a habitat for a large variety of microbes (phyllobiome), with microbial densities of up to 10⁷ cells cm⁻² (203), but the impacts of elevated O₃ or other air pollutants on the phyllobiome are poorly known (169). Rhizospheric and phyllospheric microbiotas are interconnected and overlap with endophytic microbiota through regulatory traits, particularly for the promotion of plant growth (hormone biosynthesis) and catalytic pathways (degradation of C-based and defensive compounds) (120). A preliminary study did not detect significant effects of O₃ on the phyllosphere microbiome; however, it was conducted in an artificial environment, outside the natural habitat of rice, where plants were grown in pots inside a greenhouse (169). Hence, new research is needed for understanding the impacts of elevated O₃ on the phyllobiome.

CONCLUSIONS

Despite several uncertainties, some key conclusions of our review are the following:

The composition of a plant community may exhibit long-term changes, and diversity may be at risk, due to a genotype-specific susceptibility to O₃, especially in areas where O₃ is at potentially phytotoxic levels. The consensus is that elevated O₃ affects plant-

community composition but if and to what extent O₃ may contribute to changes in biodiversity in terrestrial ecosystems remain unclear. Climatic scenarios for 2100 suggest that regions with high endemic richness, e.g., NH Atlantic islands in the latitude band 15° to 45°N, the Mediterranean Basin, equatorial Africa, Ethiopia, the Indian coastline, the Himalayan region, southern Asia, and Japan, are most threatened by high levels of O₃.

Ozone affects the foliar chemical composition and the composition of BVOC emissions, altering plant-insect interactions and thus threatening key ecosystem functions (e.g., plant-insect communication). O₃ can indirectly affect species abundance and the structure of insect communities.

Ozone also alters plant properties and soil processes that define plant-soil-microbe interactions and PSFs, such as the input of plant litter, plant exudation, root turnover, nutrient cycling, activities of soil enzymes, and decomposition, threatening the functioning of the soil ecosystem. Soil microbial communities can be indirectly affected, including decreasing microbial biomass, altering the composition and structure of communities and usually reducing alpha diversity.

The responses of plant-insect interactions and PSFs to O₃ are species specific and affected by several factors, such as the spatial variation of O₃, temperature, relative humidity, degree of urbanization, and the quality of control services in urban, rural, and forested areas. Ozone has, nonetheless, been demonstrated to decouple plant-insect interactions and PSFs, which should be considered when predicting the impacts of climate change.

Potential threats of elevated O₃ to biodiversity and ecosystem services should be considered when adopting the post-2020 global biodiversity initiative “Roadmap for EU Biodiversity Strategy to 2030” at the UN Biodiversity Conference in Kunming, China (October 2020), for curtailing biodiversity loss and preserving and restoring its ecosystems.

Acknowledgments: We are grateful to H. Kreft, Professor at the University of Bonn, Germany, for providing the dataset of endemic richness and for helpful suggestions. This paper was prepared within the International Union of Forest Research Organizations (IUFRO) Research Group 8.04.00 “Air Pollution and Climate Change” and under the Working Party 8.04.05 “Ground-level ozone.” **Funding:** Z.F., E.A., X.Y., and Z.L. acknowledge funding from the National Natural Science Foundation of China (nos. 41771034, 31950410547, 41907383, and 31901159). E.A. and Z.F. acknowledge multiyear support from The Startup Foundation for Introducing Talent of Nanjing University of Information Science and Technology (NUIST), Nanjing, China (no. 003080 to E.A. and no. 002992 to Z.F.). E.O. acknowledges funding from the Academy of Finland (BETUMICS project 284931). J.D.B. acknowledges funding from Academy of Finland decision number 309425. V.C. thanks the project ELEMENTAL (CGL 2017-83538-C3-3-R, MINECO-FEDER). J.P. acknowledges the European Research Council Synergy grant ERC-SyG-2013-610028 IMBALANCE-P. The sponsors were not involved in the study design; the collection, analysis, or interpretation of the data; the preparation of the

manuscript; or the decision where to submit the manuscript for publication. **Author contributions:** E.A., Z.F., and E.P. initially designed the study. E.A. had a leading role, served as the hub of communication among the authors, and supervised the production of the manuscript. E.A., E.O., Q.W., V.A., and J.D.B. reviewed the literature. E.A. drafted Introduction. E.O. and E.A. each drafted a version of the plant section, with inputs from F.H., and generated the final section. Z.F., E.P., M.D., C.J.S., V.C., M.V., and H.H. reviewed the plant section. P.S. and A.D.M. conducted the analyses of global O₃ exposure and plant diversity and wrote the results with inputs from E.A. V.A., J.D.B., and E.A. drafted the section on insects, with inputs from Z.L. and X.Y. V.C., E.P., and C.J.S. reviewed the section on insects. Q.W. drafted the section on microbes, with inputs from E.A. S.D.V., J.P., and J.D.B. reviewed the section on the microbiota. E.O., Z.F., and E.A. drafted the “Unresolved questions” section. E.A. created Table 1 and table S1 and drafted Abstract and Conclusions. P.S. created Fig. 3 and Table 2. C.J.S. created Figs. 1 and 2 with inputs from E.A. E.A. and Z.F. edited all reviewed sections and produced an integrated manuscript. All co-authors reviewed the integrated manuscript, substantially contributed intellectual input, and approved the final version for publication. **Competing interests:** The authors declare that they have no competing interests. **Data and materials availability:** All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.
