Introduction
Speciation is a process that occurs as inherent (i.e., non-geographic) barriers to gene flow evolve between formerly interbreeding populations. Barriers to gene flow accumulate over time and evolve most readily if populations experience geographic isolation or divergent selection (Mayr 1942; Endler 1977; Schluter 2001; Coyne and Orr 2004; Rundle and Nosil 2005). Whereas some barriers to gene flow are the consequence of differences in chromosome structure or intrinsic genetic incompatibilities, barriers to gene flow often result from divergent selection and local adaptation (Schemske and Bradshaw 1999; Rundle et al. 2000; Jiggins et al. 2001; Nosil et al. 2002; Schluter 2009). Specifically, recent empirical studies indicate that the process of ecological speciation, whereby divergent selection between populations occupying different ecological niches causes barriers to gene flow to evolve, is common (Schluter 2009), and the effects of adaptive phenotypic differences on gene flow have been quantified (e.g., Ramsey et al. 2003; Martin and Willis 2007; Lowry et al. 2008; Dell’Olivo et al. 2011).

The degree of ecological or phenotypic divergence among populations and the number and strength of barriers to gene flow vary continuously (Endler 1977; Schluter 2000; Mallet et al. 2007; Nosil 2007). Early in the speciation process, populations exhibit weak phenotypic divergence and limited reproductive isolation. Speciation can proceed by (1) the strengthening of individual barriers to gene flow due to increased phenotypic divergence in one or a few traits; (2) the evolution of additional barriers to gene flow by the onset of phenotypic
Phenotypic Divergence and Speciation

Z. Gompert et al.

North American *Lycaenidae* butterflies are well-suited for the study of phenotypic divergence during the speciation process. Five nominal species of *Lycaenidae* occur in North America and are descended from one or a few Eurasian ancestor(s) that colonized North America about 2.4 million years ago (Nabokov 1949; Guppy and Shepard 2001; Gompert et al. 2006, 2008; Forister et al. 2011; Vila et al. 2011). We focus on two of these species, *L. idas* and *L. melissa*, and in particular on a geographic region of secondary contact between these nominal species in the central Rocky Mountains (Gompert et al. 2010). In this region, *L. idas* populations occupy wetter forest and montane habitat, whereas *L. melissa* populations are found in drier sites and are often associated with agricultural fields (Fig. S1; Gompert et al. 2010). Many *L. idas* populations in this geographic region feed on *Astragalus miser* as larvae. Conversely, many *L. melissa* populations in the Rocky Mountain region feed on cultivated or feral alfalfa (*Medicago sativa*), although some populations feed on native host plants, such as *Astragalus bisulcatus*. *Lycaenidae* idas populations have a single brood and fly from mid-July to mid-August (personal observation), whereas *L. melissa* populations have a long flight season (adults fly from early June until September) that includes multiple broods. *Lycaenidae* idas and *L. melissa* populations also differ morphologically, particularly with respect to aspects of male genitalia morphology and wing pattern (Nice and Shapiro 1999; Fordyce et al. 2002; Lucas et al. 2008; Gompert et al. 2010). Barriers to gene flow between *L. idas* and *L. melissa* are incomplete (Gompert et al. 2010, 2012). Specifically, *L. idas* and *L. melissa* hybridized in Jackson Hole valley and the Gros Ventre mountains of northwestern Wyoming following secondary contact within the last 14,000 years (Nabokov 1952; Harris et al. 1997; Gompert et al. 2010). Presently, Jackson Hole valley and the Gros Ventre mountains are occupied by a series of admixed *Lycaenidae* populations that are geographically disjunct from nearby, nonadmixed *L. idas* and *L. melissa* populations (evidence of admixture comes from AFLP markers, thousands of DNA sequence loci and morphological data; Gompert et al. 2010, 2012). Hereafter, we refer to these admixed populations collectively as Jackson Hole *Lycaenidae*. Jackson Hole *Lycaenidae* are found in *L. idas*-like habitat, use *A. miser* as a larval host plant, and are more *L. idas*-like in their overall genomic composition (Gompert et al. 2010, 2012). The existence of these admixed populations demonstrates that reproductive isolation between *L. idas* and *L. melissa* is incomplete. Moreover, the admixed populations allow us to contrast phenotypic divergence between *L. idas* and *L. melissa* populations with phenotypic variation in hybrids. This contrast is informative regarding the efficacy of phenotypic differences as barriers to gene flow.
Herein, we quantify behavioral and ecological divergence among central Rocky Mountain *Lycaeides* populations to begin to address three questions: (1) does phenotypic divergence between *L. idas* and *L. melissa* occur in very few (one or two) or many dimensions; (2) do phenotypic differences likely reduce gene flow between *L. idas* and *L. melissa* populations; and (3) do *L. idas* and *L. melissa* operate as cohesive evolutionary units or are putative barriers to gene flow polymorphic and generally weaker.

**Methods**

**Oviposition preference experiments**

We conducted two sets of experiments to measure female oviposition preference. During the first set of experiments (OP1), we investigated whether females discriminate among potentially suitable host plants using short-range tactile or chemical stimuli when laying eggs. We collected gravid female *Lycaeides* from nine populations during July and August of 2009 and 2010 (Fig. S1; Table 1). We identified host plant(s) used by each population based on direct observation of female oviposition, observation of larval feeding, or an association of adult butterflies with the plants (Table 1). We placed individual females in 475 cm$^3$ oviposition chambers, constructed from plastic drinking cups covered with bridal veil. We presented these female *Lycaeides* with two (Sinclair, WY) or three (all other populations) potential host plants. For each population, we presented females with the host plant(s) used by that population and one or two other legume plants growing in or near the geographic area occupied by the population (we selected plants from the genera *Astragalus*, *Hedysarum*, *Medicago*, or *Oxytropis*, which are used as host plants by *Lycaeides* butterflies; Scott 1986). We included *M. sativa* in all experiments, as it was found in abundance near most sites. See Fig. 1 for the specific plants we used for each population. We used only fresh plant material. We removed flowers from the plant material prior to use to control for known effects of flowers on female oviposition preference in *Lycaeides* (Forister et al. 2009). We placed a few sprigs of host plant material from each plant through small holes in the bottom of oviposition chambers so that their stems had access to a common water reservoir. We included approximately equal amounts of material (based on leaf-area) from each plant. We fed female butterflies Gatorade™ ad libitum as an artificial nectar source, which we applied directly to the bridal veil. We placed the oviposition chambers under large halogen lights for approximately 14 h each day to provide light and heat (because of logistical constraints the length of time that oviposition chambers were exposed to halogen lights each day varied from 13 to 15 h). We removed female butterflies from the oviposition chamber after 2 days (approximately 48 h). We then counted the number of eggs laid on each host plant species by each caged female and used these data to estimate oviposition preference.

We conducted a second series of experiments (OP2) to determine whether oviposition preference varies among populations in a manner that could function as a barrier to gene flow between *L. idas* and *L. melissa* populations. We designed and carried out these experiments as described in the preceding paragraph, except we presented females from each population with two plant choices: *M. sativa* and *A. miser hylophilus*. *Medicago sativa* is the host plant of many *L. melissa* populations, whereas *Astragalus miser hylophilus* is fed on by most Jackson Hole *Lycaeides* and *L. idas* populations in Wyoming and southern Montana (ZG & LKL, personal observation). Thus, relative preference for these host plants is most relevant.
for understanding whether variation in oviposition preference is a barrier to gene flow. Moreover, because all populations were presented with the same host plant choices, we were able to easily compare experimental results among populations. We conducted this set of experiments during July and August of 2010 using females collected from 11 populations (four *L. idas*, three *L. melissa*, and four Jackson Hole *Lycaeides*).

We used hierarchical Bayesian models to estimate parameters that describe individual (butterfly) oviposition preference, population-level oviposition preference, and interindividual variation in oviposition preference. For both oviposition experiments, we assumed that the number of eggs laid on plant species *j* by female *i* (x*ij*) followed a multinomial distribution with parameters *p* *ij* and *n* *ij*. We ignore possible intraspecific variation in plant quality. We equate *p* *ij* with the individual-level oviposition preference of female *i* for plant species *j*. *n* *ij* denotes the total number of eggs laid by female *i*. We specified a Dirichlet conditional prior for the individual-level oviposition preference parameters (i.e., the collection of *p* *ij*) for each population:

\[
P(p|\pi, w) = \frac{1}{B(\pi w)} \prod_j \frac{p_{ij}^{x_{ij} - 1}}{\pi_j^{x_{ij} - 1}},
\]

where *π* *j* is the population-level oviposition preference for plant *j* (i.e., the probability of ovipositing on plant *j*), *w* is a scalar parameter that defines the interindivudual variation in oviposition preference (lower values of *w* correspond to increased interindividual variation), and *B* is the Beta function. We assigned uninformative Dirichlet (*π*) and uniform (*w*) hyperpriors to complete the specification of the Bayesian model. We used Markov chain Monte Carlo (MCMC) to estimate posterior probability distributions for all model parameters. We performed a separate analysis for each population and obtained parameter estimates using the R package bayespref (Fordyce et al. 2011; R Development Core Team 2011). We ran two 50,000 iteration chains for each population and discarded the first 5000 samples from each chain as a burn-in. We examined sample history plots and calculated Gelman and Rubin’s convergence diagnostic to ensure convergence of the chains to the posterior distribution (Gelman and Rubin 1992; Plummer et al. 2006). We ran a second set of analyses for the first set of oviposition experiments (OP1), which included the natal host plant(s) and one or two additional possible host plants for each population, to explicitly test the hypothesis that female *Lycaeides* discriminate among possible host plants. For this set of analyses, we imposed the constraint *π* 1 = *π* 2 = *π* 3 = 1/3, and used Deviance Information Criterion (DIC) to compare the constrained and unconstrained models (Spiegelhalter et al. 2002; Fordyce et al. 2011). For both sets of oviposition preference experiments, we tested the hypothesis that females preferred one plant over another by calculating *P*.
Mate preference experiments

We conducted two sets of experiments to assess whether male *Lycaeides* discriminate in their propensity to initiate courtship with females based on variation in female wing pattern. For both sets of experiments, we measured male courtship approaches to paper wing pattern models. Male *Lycaeides* initiate courtship. Receptive females are stationary, usually perched on or near the host plant and assume a characteristic head-down posture with their wings closed exposing the ventral surface (Pellmyr 1983). Patrolling males approach and flutter around stationary females while releasing pheromones. This initial approach can be followed by a series of courtship behaviors and lead to copulation (Pellmyr 1983). A previous study of *Lycaeides* butterflies indicates that males readily approach and court paper wing pattern models (Fordyce et al. 2002).

During the first set of experiments (MP1) we investigated whether males discriminated among females based on the size or position of wing pattern characters. We removed wings from 21 wild-caught female *Lycaeides*, and generated digital images of the ventral surface of the wings using an Epson Perfection 3170 PHOTO scanner (Epson America, Inc., Longbeach, CA). We quantified wing pattern variation for these 21 female *Lycaeides*. Specifically, we measured the size (area) and position of 24 wing pattern characters using ImageJ (Fig. S2). We estimated the area of each character using the outline tool in ImageJ. We determined character positions (i.e., centroid of each character) by calculating the mean of the x and y coordinates of all pixels making up each wing pattern character. We then used MorphoJ to perform a Procrustes fit with the centroids, and obtain Procrustes position coordinates (Klingenberg 2011). Two wing pattern characters, Cu2(3) and Rs, were absent in one or more of the females and were removed from all subsequent position-based analyses (these characters were included in area-based analyses). Previous studies have shown that *Lycaeides idas* and *L. melissa* females differ slightly in the size of wing pattern characters (Gompert et al. 2010). Wing pattern area measurements for these 21 females span the range of variation observed in *Lycaeides* populations in the Rocky Mountains (Gompert et al. 2010).

We corrected the color of the digital wing images using a scanned gray scale and the automatic color adjustment feature in Photoshop CS4 version 11.01. We printed the color-corrected wing images on Matte paper using an Epson Stylus printer (Epson America, Inc., Longbeach, CA). We then built wing pattern models by gluing together the hind and fore-wings prints and attaching them to wooden skewers. We used these models to test whether males from six *Lycaeides* populations (Fig. S1; Table 1) discriminated among females based on the wing pattern characters. We conducted these experiments in the field during July and August of 2009 between the hours of 10 am and 5 pm. For each trial, we haphazardly selected three wing pattern models with notable differences in the size wing pattern elements and placed them...
in a triangle configuration (models were placed approximately 10–30 cm apart) in the vicinity of a host plant and patrolling males. We then observed and recorded the number of times an individual male approached each of the wing pattern models. We recorded an approach when the male altered its flight path and fluttered around the female wing pattern model (Supplemental Video 1). Each male was captured once it left the array to prevent multiple visits by the same male. We selected a new haphazard set of wing pattern models after a male approached and left the experimental array. We used the approach data and morphometric measurements of the models to determine whether males preferentially approach females based on the size or position of wing pattern characters.

We conducted a second set of male preference experiments (MP2) to test the hypothesis that males more readily approached conspecific female wing pattern models than heterospecific wing pattern models. We conducted this second set of experiments in July and August of 2010, and tested males from four L. idas populations, two L. melissa populations, and four Jackson Hole Lycaeides populations. These experiments were generally similar to those described in the preceding paragraphs, but differed in several important ways. For this set of experiments, we were not interested in specific wing pattern characters per se, but rather any aspects of the wing pattern, including subtle variation in color, that might differ between L. idas and L. melissa and could lead to a conspecific mate preference. We have previously quantified differences between L. idas and L. melissa females in the size and position of wing pattern elements (Gompert et al. 2010). Ultraviolet aspects of wing pattern are not captured by the wing pattern models; however, ultraviolet wing patterns are generally lacking in the Polyommatinae (the Lycaenid subfamily that includes Lycaeides; Scott 1986). Paper wing prints were made for 15 L. idas and 15 L. melissa females by Fine Printing (Fort Collins, CO), a company that specializes in color reproductions and prints of fine artwork. Wings were photographed under constant, color-balance lights using a 15-min exposure. Colors were manually adjusted through iterative prints using a printer that was calibrated for the same computer used for adjusting colors. Final paper wings were printed on premiere smooth paper. We constructed wing pattern models from these prints as described previously. We did not quantify the color of wing models or compare the spectral reflectance of the paper wing models to the spectral reflectance of actual female butterfly wings using a model of butterfly vision (e.g., Blackiston et al. 2011). Thus, we cannot be certain that aspects of wing pattern color perceived by male butterflies were captured by the paper wing pattern models. For each trial, we used a pair of paper wing pattern models, one L. idas model and one L. melissa model, placed approximately 10–30 cm apart. We recorded male approaches as described previously and haphazardly selected a new pair of wing models after a male approached the array. We used the number of approaches to L. idas and L. melissa wing models to estimate male mate preference.

Our aim for the first set of male mate preference experiments (MP1) was to investigate whether males more readily approach female wing pattern models occupying a specific portion of morphospace. We quantified wing pattern morphospace using the first two principal components for the area or position of wing pattern characters. PC1 and PC2 explained 63.72% (area) and 50.70% (position) of the variation in model wing pattern. We fit the PC1 and PC2 scores for the presented and approached wing pattern models to a bivariate normal distribution using the mvm function in the R package mclust (Fraley and Raftery 2006). We then calculated the Kullback–Leibler divergence (DKL; Kullback and Leibler 1951) between the bivariate morphospace of the presented and approached wing pattern models, as:

$$D_{KL}(N_p || N_a) = 0.5 \left( \text{tr}(\Sigma_a^{-1} \Sigma_p) + (\mu_a - \mu_p)^T \Sigma_a^{-1} (\mu_a - \mu_p) - \log \left( \frac{\det \Sigma_p}{\det \Sigma_a} \right) - 2 \right).$$

In this equation $N_p(\mu_p, \Sigma_p)$ is a bivariate Normal distribution describing the area or position of wing pattern characters for models presented to male Lycaeides; similarly, $N_a(\mu_a, \Sigma_a)$ denotes the morphospace of approached wing pattern models. The Kullback–Leibler divergence is affected by differences in the mean and variance of approached wing pattern models. The Kullback–Leibler divergence is not sensitive to male preference for extreme or intermediate wing patterns. We generated a null distribution of $D_{KL}$ by sampling randomly and with equal probability one of the three wing pattern models presented to each male for each trial. We repeated this procedure 1000 times for each population, and calculated $D_{KL}$ for each simulated data set assuming the randomly sampled models were “approached.” We then compared the simulated, null distribution of $D_{KL}$ to $D_{KL}$ for the observed results. This procedure allowed us to test whether the difference in morphospace between the presented and approached wing pattern models was greater than expected by chance.

For the second set of male preference experiments (MP2), we estimated population mate preference parameters, which describe the relative probability of a male approaching L. idas or L. melissa. We used the same Bayesian model described for the oviposition preference experiments; however, we disregarded individual-level preferences and considered male approaches rather than
instances of oviposition. We estimated model parameters using MCMC implemented in bayespref with two chains of 50,000 steps and a 5000 step burn-in for each population. We then calculated the expected log odds ratio that a random female is approached by a male of its own species assuming males and females of each species are equally abundant as:

\[
I = \log \left( \frac{P(m \times m) + P(i \times i)}{P(i \times m) + P(m \times i)} \right)
\]

where \( p(i \times m) \) is the relative probability of a \( L. idas \) male approaching a \( L. melissa \) female. The other probabilities are defined likewise.

**Diapause experiments**

*Lycaeides* diapause as neonate larvae before exiting the egg (Scott 1986). We performed experiments to test whether the propensity to enter or break diapause varied among *Lycaeides* populations. Differences in diapause dynamics could affect phenology and constitute a barrier to gene flow. We first used eggs collected from oviposition preference experiments conducted from July 7th to August 7th 2010 to determine whether *Lycaeides* populations differed in the propensity for individuals to initiate diapause (DIA). We collected eggs from *L. idas* (four populations) and Jackson Hole *Lycaeides* (five populations) within 1–2 weeks of the onset of the adult flight. *L. melissa* adults began flying in June, and thus *L. melissa* eggs were collected approximately a month into the adult flight (*L. melissa* eggs were collected from three populations). Therefore, this experiment focuses on diapause initiation for eggs laid early in the season, which is the time period that variation in diapause initiation is most relevant. All eggs laid in late summer and early fall are expected to diapause. We visually inspected eggs to ensure they were viable and then placed no more than 10 eggs from each female in a plastic weigh boat. The eggs were exposed to ambient light, temperature, and humidity for 10 days (i.e., we placed the eggs on a desktop near an open window). We recorded the number of each female’s eggs that hatched over the 10-day period and used these data to estimate population-level probabilities for diapause initiation. This estimate is upwardly biased, as a small subset eggs that failed to hatch likely died during the experiment.

We conducted a second experiment to ask whether populations varied in the length of winter conditions required before diapause termination. For this experiment, we used eggs collected during summer 2010 that were not part of the diapause initiation study. We collected most of the eggs used in this experiment concurrently with the eggs we collected for the diapause initiation study, but we collected additional eggs in mid-August 2010 from Dubois, Lander, and Sinclair populations to augment *L. melissa* sample sizes. We cleaned the eggs using a 2% Clorox Bleach \( ^{TM} \) solution to prevent fungal growth and stored them under dark and humid conditions at 2°C to simulate winter (we did not measure humidity directly, but we kept eggs in closed petri dishes with standing water). We inspected eggs periodically throughout the winter, cleaned eggs as needed, and removed eggs that were inviable (e.g., eggs that deflated or experienced a fungal infection). We removed batches of eggs from winter conditions on March 28th (April 2011 treatment; DA11), May 2nd (May 2011 treatment; DM11), and June 1st (June 2011 treatment; DJ11) 2011. We removed an approximately equal number of eggs from each female for each treatment; however, females with fewer than 10 total eggs were only included in one or two treatments. We then exposed these eggs to summer conditions (24°C, 14 h of light, and 45% relative humidity) inside a growth chamber (Percival Scientific, Inc.). We recorded the number of eggs hatching from each female (a direct metric of diapause termination) over a 10-day period. This experiment was conducted at two locations: the University of Nevada (Reno, NV) and the University of Wyoming (Laramie, WY). We chose to split eggs between two locations to avoid catastrophic egg loss from infection or freezer failure. We included the potential effect of location in the analysis.

The model is the effect of treatment \( k \) and location \( l \) on the propensity to enter or break diapause (note, this is only approximate as some eggs that fail to hatch could be inviable). We used MCMC to estimate model parameters as previously described and tested for pairwise differences in hatching probabilities by computing \( P(\pi_{hatch,popk} - \pi_{hatch,popy} > 0) \). We then specified a hierarchical Bayesian generalized linear model (GLM) to simultaneously estimate pre and postdiapause hatching probabilities, including all winter length treatments. We assumed the number of eggs hatching from female \( i \), from treatment \( k \) (i.e., DIA, DA11, DM11, or DJ11) and location \( l \) (University of Nevada or University of Wyoming) followed a binomial distribution: \( x_{ikl} \sim \text{binomial} (p_{i,kl}, n_{i,kl}) \). We further assumed that \( \log \left( \frac{p_{i,kl}}{1 - p_{i,kl}} \right) \sim \text{Normal} (\mu_{i,kl}, \tau_{i,kl}) \), where \( \mu_{i,kl} \) is the logit transformed expected value for \( p_{i,kl} \) and \( \tau_{i,kl} \) is a precision parameter that is indexed by treatment and location and describes among-individual variation in hatching probability. We defined a linear model for \( \mu_{i,kl} \):

\[
\mu_{i,kl} = \alpha_k + \beta_{i,(k,)}
\]

where \( \alpha_k \) is the effect of treatment \( k \) and \( \beta_{i,(k,)} \) is the effect of location \( l \) for treatment \( k \). We imposed a sum-to-zero
constraint on the \( \beta_k \) to ensure identifiability of the parameters. We placed independent uninformative Normal priors on the \( \gamma_k \) and \( \beta_k \). We assigned uninformative gamma priors with shape and scale equal to one on each \( \gamma_k \). We implemented MCMC estimation of these model parameters using the BRugs R interface with OpenBugs 3.2.1 (Thomas et al. 2005). For each population, we combined the samples from three independent 75,000 iteration chains following a 50,000 iteration burn-in. We calculated and assessed Gelman and Rubin’s convergence diagnostic to ensure convergence of the chains to the posterior distribution (Gelman and Rubin 1992; Plummer et al. 2006).

All necessary permits were obtained for the described field studies (USA National Park research permits YELL-2008-SCI-5682, GLAC-2009-SCI-0140 and GRTE-2008-SCI-0024).

Genetic and phenotypic divergence

We wanted to know whether genetic and phenotypic divergence among Lycaeides populations pairs were correlated. A positive correlation between genetic divergence and divergence for a phenotypic character would be consistent with the hypothesis that differences in that character limit gene flow among populations, or that gene flow constrains adaptive or neutral character divergence (Nosil 2009). It is common to compare genetic and phenotypic divergence by comparing \( F_{ST} \) and \( Q_{ST} \) (e.g., Palo et al. 2003; Kawakami et al. 2011; Ovaskainen et al. 2011). These comparisons address a related, but distinct question, namely whether phenotypic divergence is a consequence of divergent selection, and are beyond the scope of this current study. We quantified genetic divergence between pairs of Lycaeides populations based on 17,693 DNA sequence loci, which were described and analyzed by Gompert et al. (2012). We measured genetic divergence based on estimates of the genome-level evolutionary parameter \( F \) assuming a hierarchical Bayesian F-model (Gompert et al. 2012). The parameter \( F \) is analogous to \( F_{ST} \) under an island model at equilibrium or a model of neutral divergence from a common ancestral population (Balding and Nichols 1995; Nicholson et al. 2002; Falush et al. 2003; Gaggiotti and Foll 2010). We estimated \( F \) for each pair of populations using MCMC as described by Gompert et al. (2012). We based inferences on the concatenated samples from two independent MCMC chains per population, each iterated for 25,000 steps with a 1000 step burn-in.

We calculated the oviposition preference distance between each pair of populations as the absolute difference in their point estimates of female preference for A. m. hylophilus (\( \pi_{A.m.hydrophilus} \)) based on the second set of oviposition preference experiments (OP2). Likewise, we calculated male mate preference distance for each pair of populations as the absolute difference in the point estimates of male preference for L. idas paper wing models (MP2; \( \pi_{L.idas} \)). We then calculated diapause initiation distance for each pair of populations as the absolute difference in estimates of the probability of eggs hatching without over-wintering from the summer 2010 diapause experiments (DIA; \( \pi_{hatch} \)). We also quantified distances among populations based on two morphological characters, male genitalia morphology and wing patterns. We reported variation in these morphological characters in a previous publication (Gompert et al. 2010). Previously, we measured the length of three components (forearm, humerulus, and uncus) of the sclerotized portion of the male genitalia anatomy for 149 individuals sampled from the populations included in the current study (Gompert et al. 2010). This structure is thought to be important for copulation in Lycaeides (Nabokov 1949; Nice and Shapiro 1999; Lucas et al. 2008), and the geographic cline in male genitalia anatomy in the Rockies is displaced to the northwest relative to the geographic cline in admixture proportion (Gompert et al. 2010), which suggests that variation in male genitalia morphology could affect fitness. We used PCA to rescale and rotate the three length measurements and generate a single variable that describes male genitalia size and explains 81% of the variation in the original measurements. We previously reported variation in wing pattern in Lycaeides based on 23 wing pattern characters, which include the standardized area of the wing pattern elements described in the mate preference methods section and the distance between pairs of elements (Gompert et al. 2010), but we reanalyze only the 18 area measurements. We used PCA to reduce the dimensionality of these 18 measurements and extract a single variable describing wing pattern. We performed a separate PCA for males (74 individuals) and females (43 individuals). The first principal component explained 44.4% (males) or 49.7% (females) of the variation in the measured wing pattern elements and corresponded to wing pattern element size. We then calculated male genitalia distance and wing pattern distance between each pair of populations as the absolute difference in their mean PC1 scores.

Geographic distance is often correlated with genetic distance; hence, we first tested for a correlation between pairwise geographic and genetic distances among populations using a Mantel test. We then conducted partial Mantel tests to determine whether genetic distance was correlated with (1) oviposition distance; (2) mate preference distance; (3) diapause initiation distance; (4) genitalia distance; (5) male wing pattern distance; and (6) female wing pattern distance while controlling for geographic distance. We controlled for geographic distance...
by first regressing genetic and phenotypic distance on geographic distance and then testing for a correlation between residual genetic and residual phenotypic distance. We conducted the Mantel and partial Mantel test in R using the mantel.test function from the ade4 package and code written by the authors (Dray and Dufour 2007; R Development Core Team 2011). Finally, we used multiple regression on distance matrices (MRM) to regress the genetic distance matrix on the geographic distance matrix and all phenotypic distance matrices simultaneously (Legendre et al. 1994; Lichstein 2007). We used the R function MRM from the ecodist package for the MRM analysis. For each analysis, we performed 10,000 permutations to assess the significance of the estimated correlation or regression coefficients. We conducted a second set of partial Mantel tests to account for uncertainty in the estimates of oviposition distance, mate preference distance, and diapause distance. Specifically, we iteratively (1000 iterations) sampled preference or diapause parameters from the posterior distribution for each population and recalculated the distance matrix. We implemented the partial Mantel test on each recalculated distance matrix to obtain Monte Carlo estimates of the correlation coefficient and p-value associated with each character.

Results

Oviposition preference

Many Lycaeides populations discriminated among potential host plants, but not always in favor of their natal host plant (results from OP1; Fig. 1). Four of the nine populations laid the most eggs on their natal host plant(s). For example, females from the Sinclair L. melissa population strongly preferred to oviposit on their native host plant, A. bisulca-tus, relative to M. sativa (Fig. 1). Conversely, females from the Victor L. melissa population did not discriminate among plant species, and females from the Siyeh Creek L. idas population preferred to oviposit on M. sativa, which is a plant that they do not use in the wild.

The second set of oviposition preference experiments (OP2) included two host plants: A. m. hylophilus and M. sativa. Lycaeides melissa populations displayed a slight preference for ovipositing on M. sativa (\(\pi_{A.m,hylophilus} < 0.5\)), although this trend only obtained strong statistical support for the Victor population (Fig. 2A). Lycaeides idas populations varied considerably in their relative oviposition preference for M. sativa and A. m. hylophilus (Table 2). For example, Hayden Valley L. idas females clearly preferred to oviposit on A. m. hylophilus (\(\pi_{A.m,hylophilus} = 0.66\)), 95% equal-tail probability interval (ETPI) = 0.58–0.73), whereas Garnet Peak L. idas did not have a clear preference and Siyeh Creek L. idas preferred to oviposit on M. sativa. Jackson Hole Lycaeides populations also varied in oviposition preference, but three of the five populations clearly preferred A. m. hylophilus relative to M. sativa (\(P[\pi_{A,m,hylophilus} - \pi_{M,sativa} > 0] \geq 0.95\); Fig. 2A, Table 2). Oviposition preference was consistent among females in some populations (e.g., Teton Science School and Hayden Valley), whereas females from other populations varied considerably in oviposition preference (e.g., Victor and Bunsen Peak; Figs. 2B, S3).

Mate preference

Male butterflies approached the paper wing pattern models (Video S1). We found little to no evidence that males preferentially approach paper wing models based on the size (area) of wing pattern characters, as the subset of morphospace sampled by patrolling males was not different from random expectations (Fig. 3; MP1). However, for all six populations the mean value of wing pattern area PC1 for female wing models approached by males relative to all presented female models shifted in the expected direction (i.e., more L. melissa-like for the Victor L. melissa population and more L. idas-like for the five Jackson Hole and L. idas populations; \(P = 0.016\) from a binomial distribution with \(\pi = 0.5\) and \(n = 6\)). A single L. idas population, Trout Lake, displayed a significant preference for a subset of morphospace with respect to the position of wing pattern characters (KL divergence = 1.034, \(P = 0.039\); Fig. S4; MP1). Males from this population more readily approached females with black spots closer to the distal region of the wing. This result would not be significant following a Bonferroni correction.

Males from two Jackson Hole Lycaeides populations (Blacktail Butte and Mt. Randolf) were significantly more likely to approach L. idas wing pattern models than L. melissa wing pattern models (\([\pi_{L.idas} - \pi_{L.melissa} > 0] \geq 0.95\); Fig. 4A; MP2). Males from all other populations did not have a significant preference, although limited evidence suggests that males from both L. melissa populations more readily approached L. melissa wing pattern models (\(\pi_{L.idas} < 0.5\)), whereas estimates of \(\pi_{L.idas}\) were greater than 0.5 for two L. idas and two Jackson Hole Lycaeides populations, but less than 0.5 for the other two L. idas and two Jackson Hole Lycaeides populations (Table 3, Fig. 4A). The 95% ETPI for the log-transformed expected pairing ratio include zero for all L. idas × L. melissa population pairs (Fig. 4B).

Diapause

Most L. melissa eggs hatched without over-wintering (Sinclair, \(\pi_{hatch} = 0.82\); Lander, \(\pi_{hatch} = 0.85\); Victor \(\pi_{hatch} = 0.75\); Fig. 5, Table 4; DIA). Many L. melissa eggs
that did not hatch within the 10-day period appeared deflated and dead. Conversely, no L. idas or Jackson Hole Lycaeides eggs hatched without diapausing (Fig. 5, Table 4). After exposure to winter conditions and regardless of treatment, a subset of eggs from all populations except Upper Slide Lake hatched (Fig. 6). For many populations, the probability of hatching after over-wintering was greatest in the April 2011 treatment (mean across all populations; \( p_{\text{hatch}} = 0.44; \ DA11 \)) and declined in the May 2011 (DM11) and June 2011 (DJ11) treatment. Conversely, hatching probabilities were fairly consistent across all treatments for some populations (e.g., Blacktail Butte).

**Genetic and phenotypic divergence**

We detected a significant correlation between geographic and genetic distance (Mantel test, \( r = 0.77, P < 0.0001; \).
After controlling for the effect of geographic distance, we found strong evidence for increased genetic differentiation associated with differences in diapause initiation (partial Mantel test, $r = 0.81$, $P = 0.0018$), male genitalia size (partial Mantel test, $r = 0.80$, $P = 0.0411$), and male wing pattern (partial Mantel test, $r = 0.75$, $P = 0.0350$), and more moderate evidence for increased genetic differentiation associated with differences in oviposition preference (partial Mantel test, $r = 0.35$, $P = 0.0198$; Fig. 7B–F). We did not detect a significant association between genetic distance and male mate preference or female wing pattern. The correlation between diapause initiation distance and genetic differentiation was robust to uncertainty in diapause initiation parameters (Monte Carlo partial Mantel test, $r = 0.78$ ETPI 0.71–0.83, $P = 0.0016$ ETPI 0.0008–0.0023), whereas the correlation
between oviposition preference distance and genetic distance was affected by uncertainty in population preference parameters (Monte Carlo partial Mantel test, $r = 0.25$ ETPI - 0.08–0.59, $P = 0.0729$ ETPI 0.0030–0.6454). Based on the MRM analysis, geographic distance combined with all phenotypic distances explained 98.1% of the variation in genetic distances ($P = 0.0013$). Regression coefficients for diapause initiation distance ($P = 0.0150$) and male wing pattern distance ($P = 0.0429$) were significantly different from zero.

**Discussion**

The nominal butterfly species *L. idas* and *L. melissa* have diverged along multiple (more than one or two) phenotypic axes. Importantly, phenotypic divergence along multiple axes does not necessarily imply multifarious selection during speciation, but rather could reflect the sequential accumulation of phenotypic divergence along multiple axes once some degree of inherent or geographic isolation exists. We detected pronounced phenotypic
Figure 5. Estimated population-level probability of summer-brood eggs hatching without over-wintering (DIA). Points and error bars denote the median and 95% equal-tailed probability intervals for parameter estimates. Vertical dotted black lines separate Lycaeides melissa (far left), Jackson Hole Lycaeides (center), and Lycaeides idas (far right) populations and the dashed gray line denotes a hatch probability of 0.5. Different letters denote posterior probability ≥ 0.95 for differences in prewinter hatch probability. See Table 1 for population abbreviations.

correlation between genetic distance and phenotypic divergence could arise if phenotypic divergence causes reduced gene flow, or reduced gene flow allows phenotypic divergence by neutral or adaptive processes (Nosil 2009). Moreover, divergence along additional phenotypic axes that we have not considered could reduce gene flow between L. idas and L. melissa and be correlated with the characters we measured. Despite detectable phenotypic divergence along multiple axes, reproductive isolation between L. idas and L. melissa is incomplete, as evidenced by the existence of admixed Jackson Hole Lycaeides. Thus, continued hybridization between these nominal species could erode current genetic and phenotypic divergence, or further divergence could strengthen current barriers to gene flow or cause new barriers to evolve completing the speciation process (Nosil et al. 2009). Uncertainty in the future evolutionary independence of L. idas and L. melissa is exacerbated by the fact that many of these barriers to gene flow are environment-dependent. The future efficacy of these barriers could be affected, for example, by possible changes in the distribution and abundance of alfalfa (M. sativa) or changes in regional climate (Lucas and Gompert 2011).

Jackson Hole Lycaeides occupy L. idas-like habitat, feed on the same host plant as nearby L. idas populations (A. miser), possess L. idas-like wing patterns, and have a more L. idas-like genomic composition (Gompert et al. 2010, 2012). Our current results demonstrate that Jackson Hole Lycaeides are also more L. idas-like with respect to

diapause initiation, oviposition preference, and to a lesser extent male mate preference. These findings are consistent with the hypothesis that ecological and behavioral divergence between *L. idas* and *L. melissa* was caused by local adaptation to habitat (diapause initiation), host plant (oviposition preference), or mate recognition (male mate preference), and that these phenotypic differences are barriers to gene flow. In other words, the fact that *L. idas* and Jackson Hole *Lycaedes* occupy similar niches and possess similar ecological and behavioral traits suggests that these similarities are the result of selection following admixture and that migrant *L. idas* or *L. melissa* individuals would suffer reduced fitness in heterospecific populations. Reduced migrant fitness is a major barrier to gene flow between many ecologically divergent taxa (e.g., Mallet and Barton 1989; Via et al. 2000; Nosil 2004).

Interestingly, we detected the highest population-level preference for ovipositing on *A. miser hylophilus* in several of the Jackson Hole *Lycaedes* populations and a single *L. idas* population in Hayden Valley. The Hayden Valley population is on the northern edge of the range of the admixed Jackson Hole *Lycaedes* populations. Similarly, we only detected significant male mate preference in two populations. Both were Jackson Hole *Lycaedes* populations with male butterflies that more readily approached *L. idas* wing pattern models. Thus, we found some evidence that *Lycaedes* from populations with recent histories of hybridization have stronger oviposition or mate preference. These results could be explained if selection against hybridization with *L. melissa* caused stronger oviposition or male mate preference in these populations (i.e., reinforcement). Given these results and increased evidence of reinforcement from a growing list of other taxa (e.g., Lukhtanov et al. 2005; Nosil 2007), the possibility of reinforcement in *Lycaedes* certainly deserves further investigation. However, as we are currently unaware of the genetic architecture of the phenotypic traits described in this study, and particularly the effects of environment, dominance or epistatic interactions on phenotype, any adaptive explanation of phenotypic variation in Jackson Hole *Lycaedes* is tentative. For example, if alleles conferring an *L. idas*-like phenotype are dominant to alleles conferring an *L. melissa*-like phenotype one would predict Jackson Hole *Lycaedes* to display more *L. idas*-like phenotypes even if both alleles occur at intermediate frequencies.

We found evidence of both consistent and inconsistent phenotypic divergence between pairs of *L. idas* and *L. melissa* populations. For example, variation in diapause initiation was partitioned almost entirely between taxa, whereas oviposition preference was variable between species and among conspecific populations. Traits that differed to a greater extent between individual pairs of heterospecific populations, differed less among conspecific populations. For example, many individual pairs of *L. idas* and *L. melissa* populations differed considerably in diapause initiation and male genitalic morphology and these traits differed little among conspecific populations (Gompert et al. 2010). Conversely, oviposition preference and male mate preference differed less between individual *L. idas* and *L. melissa* populations, but differed to a greater extent among conspecific populations. This pattern would be expected if weak barriers to gene flow initially arise within individual populations, then spread among conspecific populations, and later strengthen through additional phenotypic divergence. In contrast, a strong barrier to gene flow that arises within a single population does not spread, but instead causes further evolutionary divergence and cladogenesis. This pattern would also be expected if considerable and consistent interspecific phenotypic divergence along a single axis limits the opportunity for variability within species.

Polymorphic barriers to gene flow within species might be expected if adaptive divergence is primarily the result of new mutations, but selection is consistent across conspecific populations. Thus, an adaptive allele could arise in one population, increase in frequency via selection and spread among populations resulting in a transitory polymorphic barrier. However, a similar pattern might also be expected if adaptation occurs from standing genetic variation, but selection pressures vary among conspecific populations. It would be possible to distinguish between these mechanisms by testing for the signature of a hard selective sweep associated with the alleles responsible for adaptive phenotypic divergence (Sabeti et al. 2002; Herisson and Pennings 2005; Pritchard and Di Rienzo 2010). Polymorphic barriers to gene flow would be less likely if conspecific populations experience consistent selection pressures and adaptation occurs from standing genetic variation. For example, freshwater and marine threespine stickleback populations differ consistently in armor plate patterning. This phenotypic divergence is the consequence of adaptation from standing genetic variation at the *Eda* locus and consistent selection pressures within each ecotype (Colosimo et al. 2005; Hohenlohe et al. 2010). Clearly, whether barriers to gene flow are expected to be polymorphic within species depends on the extent that adaptation occurs from standing genetic variation rather than new mutations and the relative roles of gene flow and selection in determining whether species operate as cohesive evolutionary units (Ehrlich and Raven 1969; Slatkin 1987; Schluter and Conte 2009).

In conclusion, *L. idas* and *L. melissa* differ with respect to multiple phenotypic traits, and some of these trait differences might limit heterospecific gene flow. Importantly, we demonstrated that some potential barriers to gene flow are heterogeneous within *L. idas* and *L. melissa*.

The possibility that barriers to gene flow might be polymorphic early in the speciation processes is seldom investigated and warrants greater attention (but see, Wade et al. 1997; López-Fernández and Bolnick 2007; Good et al. 2008). Further understanding of polymorphic barriers to gene flow during the speciation process will be facilitated by the combined study of the genetic and phenotypic basis of reproductive isolation. We have begun efforts to identify genetic loci responsible for variation in these phenotypic traits. Patterns of genetic variation at these loci will provide important insights into the efficacy of these traits as barriers to gene flow and the evolution of phenotypic divergence.

Acknowledgments
This manuscript was improved by comments from four anonymous reviewers. We thank the following for help in the field: M. Diaz, R. Lund, M. Moore, K. Palmer, M. Pfeifer, and M. Spurrier. We are grateful to M. Brock for assistance developing paper wing models. We thank R. Hartman, E. Nelson, and the Rocky Mountain Herbarium for help identifying host plants. This research was facilitated by the UW-NPS field station in Grand Teton National Park and the research staff at Yellowstone, Glacier and Grand Teton National Parks (research permits YELL-2008-SCI-5682, GLAC-2009-SCI-0140 and GRTE-2008-SCI-0024).
